Abstract

Functional responses, the relationship between a consumption rate and resource density, can be categorised into three types. The first, the type I response, is a linear relationship, exhibited by some filter feeders. The second, the type II response, also known as the Holling Model or the basic functional response, is the most common and represents a response with a non-zero handling time. The third, the type III response, is the generalised functional response, from which the other two can be produced, and is linked to predator switching and learning. All three are examples of a mechanistic model, which is a model based on biological principles. In this paper, the type III response (the generalised functional response), and by extension the other two types, are compared against a phenomenological model, a polynomial, and shown to be a significantly better fit to empirical data. This provides evidence for the outperformance of mechanistic models over phenomenological models.

Those datasets that were fitted best by the generalised functional response were then subsetted into the three different functional response types in order to identify those best fitted by the Holling type I model. By reviewing these datasets in terms of feeding mode, the claim by Jeschke et al. in their 2004 paper that "type I functional responses are exclusive to filter feeders" is tested and contradicting data is found. This does not conclusively reject the claim, as there are many other factors that could have influenced this result, but rather suggests further study should be done in this area.

1 Introduction

The term functional response refers to the relationship between a consumer's consumption rate and the density of its prey (Solomon 1949). The first mechanistic mathematical approach to functional responses was conducted by Holling in 1959 (Holling 1959a). Holling constructed an artificial functional response experiment and discovered that the consumption rate is related to prey in terms of two constants: instantaneous rate of discovery and handling time. The instantaneous rate of discovery corresponds to the likelihood of a predator finding an individual prey, expressed as the volume or area searched per unit of time. The handling time is any time not spent in actively searching for prey. There have been discussions on the different physical activities that handling time includes, such as digestion, time spent consuming prey, time spent hunting prey etc. (Jeschke, Kopp, and Tollrian 2002; Holling 1966) but for the purposes of this paper, we are assuming handling time is time spent on any non-foraging activities. This functional response is the most common in nature and is known as the basic functional response (Holling 1959a).

In an earlier paper of the same year, Holling describes the shapes of the three functional responses (Holling 1959b) where his experimentally derived basic functional response can be seen to describe a type II functional response.

Other attempts at modelling functional responses have been made using different assumptions and mathematics; these are discussed by Holling in a later paper, in which he remarks on the lack of biological context in most of the other options (Holling 1965). Since then, further models have been formalised and changes made to the original Holling equations but these were not used in this paper's hypothesis and will only be considered in the discussion.

The type III functional response was modelled using computer simulations and labelled as the generalised functional response by Holling in a later paper (Holling 1965), with types I and II being limiting conditions. However, type III was not described mathematically until 1977 by Real, who derived it using Holling's type II functional response equation and first-order kinetic interactions (Real 1977).

The generalised functional response equation is written below, where c is the consumer consumption rate, a is the instantaneous rate of discovery, x is the resource density, h is the handling time and q is a variable with as yet unknown biological meaning. It has been hypothesised that q could be related to predator learning and is 'the number of encounters...a predator must have with a prey item before becoming maximally efficient at utilizing the prey item as a resource' (Real 1977).

$$c = \frac{ax_R^{q+1}}{1 + hax_R^{q+1}} \quad (1)$$

It can be shown that the type II functional response is a special case of the generalised functional

response by setting $q = 0$. In terms of Real's interpretation of q , this means that the predator 'is always maximally efficient on the prey item' (Real 1977) in a type II response.

$$c = \frac{ax_R}{1 + hax_R} \quad (2)$$

In type I, the handling time is negligible, reducing the second term in the denominator to almost zero, leaving us with a linear relationship:

$$c = ax_R \quad (3)$$

Type I responses are to be found in filter feeders, where the predation rate is directly proportional to the prey density (Jeschke, Kopp, and Tollrian 2004). This is because filter feeders are able to do activities simultaneously so can effectively spend all their time foraging. There is normally a hard cut-off at very high prey densities, indicating a maximum number of prey that can be caught. (Jeschke, Kopp, and Tollrian 2004).

This paper aims to look at whether the generalised functional response equation (a mechanistic model) or a polynomial (a phenomenological model) fits best to empirical functional response data. The polynomial has no biological meaning, so the comparison is effectively one of phenomenological vs mechanistic models. The null hypothesis is that the mechanistic model is no better than a phenomenological model and so the data will be best fit by each model roughly half the time.

By fitting both the general functional response model and a polynomial to 295 empirical datasets, the proportion of best fits by model can be compared. The functional response types were also compared by subsetting by the limiting conditions of type I and type II functional responses, i.e. filtering by the values of h and q respectively, gaining information on the split between the three types. The data can then be subsetting by different metadata fields, such as habitat, in order to look for model fitting trends.

The second part of this paper focusses on the functional response of filter feeders. In previous work, it has been shown that, although the majority of filter feeders do not show a type I response, the type I response is only possible for filter feeders (Jeschke, Kopp, and Tollrian 2004). Type I functional responses are characterised by two main conditions: handling time must be negligible and the consumer must always spend the maximal time and effort foraging, the only exception being once the gut is full (satiation condition) (Jeschke, Kopp, and Tollrian 2002). Many filter feeders have a negligible handling time because they are able to catch prey at the same time as performing other activities, resulting in effectively all of their time being spent foraging. Some filter feeders also adhere to the satiation condition but not many. Both conditions must be met in order for the functional response to be type I, but both conditions could also be met when the resulting functional response is of a different type. This is why it is claimed that the majority of filter feeders (and all non-filter

64 feeders) do not show a type 1 response (Jeschke, Kopp, and Tollrian 2004; Deville et al. 2013; Porter,
65 Orcutt Jr., and Gerritsen 1983). Here, the exclusivity of a type I response to filter feeders is explored in
66 terms of Real’s definition of q and derivation of the type III functional response, looking at functional
67 responses when q is not confined to any limits (Real 1977). It is expected that there will be full
68 adherence to the paper of Jeschke et al. and so no Holling type I responses are expected to best fit
69 any non-filter feeders.

70 **2 Methods**

71 **2.1 Data**

72 The dataset used is a collection of 4507 records, grouped into 308 IDs, each of which corresponds to
73 a different functional response. The data have been collected from various lab and field experiments,
74 conducted globally, and measure the rate of consumption of a single resource by a consumer, along
75 with various metadata, such as habitat and taxa. There are 68 fields but only 11 have been considered
76 in this paper: ID, consumption rate and resource density for fitting the models; consumer forag-
77 ing movement, resource foraging movement, habitat, experimental conditions (lab/field/enclosure),
78 resource movement dimensionality, consumer movement dimensionality, resource thermal type and
79 consumer thermal type for subsetting the data and looking for trends.

80 **2.2 Computing Tools**

81 **2.2.1 Data preparation—R**

82 Data was prepared for fitting using R v.3.6.1 (R Core Team 2019) because of the ease of viewing data
83 and of accessing and manipulating dataframes. First, the data is subsetted by the necessary columns,
84 all records with missing consumption rates and all IDs with fewer than 5 records are removed (to
85 reduce the possibility of overfitting), which leaves 295 IDs remaining. The data preparation script
86 then generates initial starting values for a and h for the general functional response fit. A new
87 dataframe, including subsetted data and initial starting values for a and h , is saved to a csv file.

88 **2.2.2 Model Fitting — Python**

89 The starting value optimisation and fitting script is done using Python v.3.7.4 (Van Rossum and Drake
90 2009). For the polynomial fit, there is an in-built Python function, which also calculates starting values
91 and fit statistics. For the general functional response fit, a Gaussian sample of 6 (chosen for speed
92 of programme execution) is generated around the estimated starting values and each combination of
93 these sample values is used to fit a model to the dataset, resulting in 36 different fits. The AIC, BIC
94 and residual sums of squares (RSS) are calculated for each ID and the starting values for the model

with the lowest AIC are chosen as the best fit (Johnson and Omland 2004). These calculations are performed for each ID using parallelisation and the best fit parameters and statistics are stored in a new dataframe and then saved as a csv for importing into R for the plotting and analysis script.

Functions are saved in a separate Python script and have been generalised to allow importing into future programmes. Two inbuilt Python packages have been used: `itertools` to try all combinations of the start values, and `multiprocessing` to allow parallelisation (Van Rossum and Drake 2009). The packages `lmfit` (Newville et al. 2014) v.0.9.14, `NumPy` (Oliphant 2006) v.1.18.1 and `pandas` (McKinney 2010) v.0.24.2 were used. `NumPy` contains the polynomial fitting function as well as different mathematical values, such as π . The package `lmfit` allows the use of parameters when fitting a model and `pandas` is a dataframe tool.

2.2.3 Plotting and Analysis — R

The plotting and analysis script has been written in R due to the ease of graphical representation in RStudio and statistical functionality. Four packages are used: `ggplot2` (Wickham 2016) for visualisation; `tidyverse` (Wickham et al. 2019) for easy data manipulation; `DescTools` (al. 2020) for statistical tests; and `janitor` (Firke 2020) to create flexible tables. After reviewing the datasets, those IDs which haven't been fitted properly are discarded. Some of the inaccurately fitted datasets have a large number of points at very low x -values and then a few at very high x -values, a logarithmic transformation could have been performed on these prior to fitting, but this option was discarded in favour of maintaining the biological significance of a and h . This left 280 IDs remaining for analysis.

The script compares RSS, AIC and BIC for each model within each ID and chooses the best fit model based on at least two out of three agreements between these statistics. RSS is used as-is instead of calculating R^2 due to the new numerous pitfalls in calculating this statistic for non-linear regressions (Kvålseth 2012). AIC and BIC were chosen because they are the currently viewed as the most appropriate best-fit statistics (Johnson and Omland 2004). The spread of best fits was compared graphically and a measure of the significance of the resulting proportion of fits between the phenomenological and the mechanistic model was obtained by performing both a G-test of goodness-of-fit and a chi-square goodness-of-fit test.

The data is then subsetting into the three Holling types by setting any ID with the generalised functional response as best fit and $-0.3 < q < 0.3$ as Holling type II, and any Holling type II with $h < 0.1$ as Holling type I. Given q is given no limits in the fitting script, 0.3 was chosen as the limiting boundary for q visually, based on whether the resulting plots exhibited a Holling type II or Holling type I shape. Plots and tables of eight different metadata fields and a table showing the proportion of best fit models in terms of feeding mode are then generated and a G-test of goodness-of-fit is performed to test the significance of the proportion of non-filter feeders best fitted by a Holling type I response.

129 2.2.4 Run Script — Bash

130 Bash was chosen to join the above scripts into a clear, reproducible workflow because it can run R
131 and Python scripts simply and easily, as well as compile latex files with references.

132 3 Results

133 3.1 Mechanistic vs Phenomenological Models

134 The findings of a comparison between the mechanistic model and the phenomenological models are
135 shown in Figure 1. It is clear that the mechanistic models are a much better fit. 95.4% of the data
136 was best fitted by the mechanistic model, which accounts for 267 of 280 IDs. This is highly significant
137 ($p < 2.2 \times 10^{-16}$ for both G-test of goodness-of-fit and chi-square goodness-of-fit test), showing that
138 the Holling mechanistic models fit empirical data much better than a polynomial.

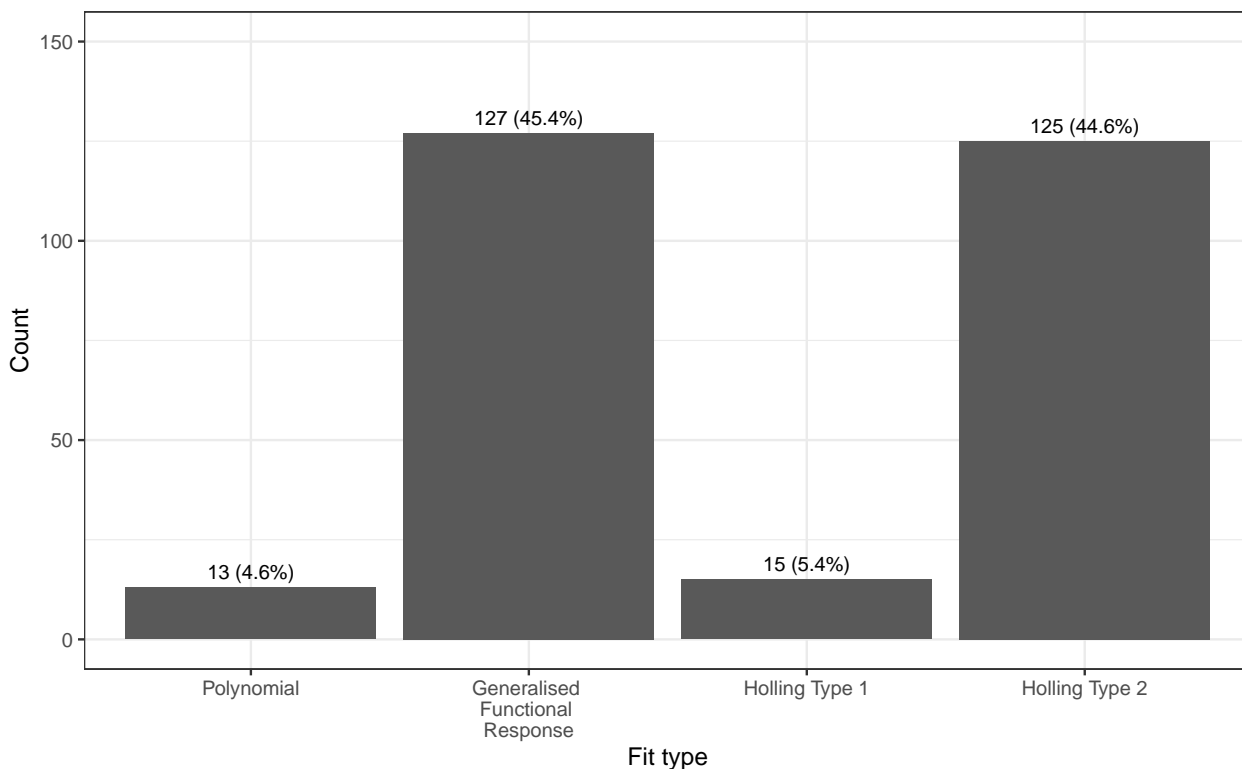

Figure 1: ID count by best fit model type

139 3.2 Data subsets

140 The dataset was preliminarily plotted in terms of eight factors: habitat, experimental conditions
141 (lab/field/enclosure), consumer and resource thermal type, consumer and resource foraging movement
142 and consumer and resource movement dimensionality. All of these had a very similar ratio between the
143 different best fits to that of the whole dataset, as can be seen from the four examples in Table 1. The

few factors with slightly more varied proportions can be explained by the low quantity of data for that trait, for example passive resource foraging movement, which has only seven records. No particular trait was best fitted by a particular model, which is why the second focus of this paper is filter feeders.

	Habitat	Poly	GFR	Holling 1	Holling 2
1	Freshwater	5% (8)	41% (68)	7% (11)	47% (77)
2	Marine	4% (2)	49% (26)	6% (3)	42% (22)
3	Terrestrial	5% (3)	52% (33)	2% (1)	41% (26)
4	Total	5% (13)	45% (127)	5% (15)	45% (125)

	Experimental Conditions	Poly	GFR	Holling 1	Holling 2
1	Enclosure	6% (1)	44% (8)	6% (1)	44% (8)
2	field	0% (0)	60% (6)	0% (0)	40% (4)
3	Laboratory	5% (12)	45% (113)	6% (14)	45% (113)
4	Total	5% (13)	45% (127)	5% (15)	45% (125)

	Resource Foraging Movement	Poly	GFR	Holling 1	Holling 2
1	active	5% (11)	42% (91)	6% (14)	46% (100)
2	passive	0% (0)	50% (4)	0% (0)	50% (4)
3	sessile	4% (2)	57% (32)	2% (1)	38% (21)

2	sessile	4% (2)	39% (20)	10% (5)	47% (24)
3	Total	5% (13)	45% (127)	5% (15)	45% (125)

Table 1: Different fit proportions in terms of various factors. The fit proportions shown by the overall data are shown at the bottom of each table.

3.3 Feeding mode

Each of the IDs best fitted by a Holling type I response was allocated a feeding mode (either filter feeder or non-filter feeder), with the aim of exploring the 2004 claim by Jeschke et al.(Jeschke, Kopp, and Tollrian 2004) that only filter feeders can display a Holling type I functional response. This allocation, along with the reference, can be seen in Table 2 and has been done according to the definition of a filter feeder in the 2004 paper by Jeschke et al. This is a very broad definition that

includes suspension feeders, trap builders, sediment filter feeders, those that only filter feed at certain stages in their lifecycle and also those that change feeding strategies according to prey abundance (Jeschke, Kopp, and Tollrian 2004). From Table 2, it is apparent that a total of 11 of the 15 IDs best fit by a Holling type I functional response are classed as non-filter feeders. This result is not insignificant ($p < 2.2 \times 10^{-16}$ using G goodness of fit test). Figure 2 shows an example of a clearly linear functional response for a non-filter feeder consumer that is best fitted by the Holling type I equation.

ID	Taxa and Lifestage	Feeding Mode with Reference
695	Stethorus punctum (Adult)	Non-Filter Feeder (Hull, Asquith, and Mowery 1977)
39839	Rhyacophila dorsalis (Second Instar)	Non-Filter Feeder (Elliott 2005)
39866	Notonecta maculata (Fourth instar)	Non-Filter Feeder (Gergs and Ratte 2009)
39890	Anomalagrion hastatum (Final Instar)	Non-Filter Feeder (Conservation 2020)
39896, 39905	Chaoborus americanus (Fourth instar)	Non-Filter Feeder (Moore 1988)
39920	Ranatra dispar (Fifth instar)	Non-Filter Feeder (Bailey 2010)
40010	Nereis (Hediste) diversicolor (Adult)	Filter Feeder (Riisgård 1994)
40019	Parabroteas sarsi (Adult)	Filter Feeder (Green and Shiel 1999)
40026	Cyclops kolensis (Adult)	Non-Filter Feeder (Kerfoot 1978)
40066	Praunus flexuosus (Adult)	Filter Feeder (Viitasalo and Rautio 1998)
40089, 40094, 40097	Sander vitreus (Juvenile)	Non-Filter Feeder (Galarowicz and Wahl 2011)
400121	Aurelia aurita (Juvenile)	Filter Feeder (Hansson 2006)

Table 2: The consumers of functional responses best fit by a Holling Type I fit. Feeding mode has been based on the definition used by Jeschke et al (Jeschke, Kopp, and Tollrian 2004)

4 Discussion

4.1 Mechanistic vs Phenomenological Models

Functional response data are much better explained by the Holling mechanistic models than by a polynomial. This was to be expected, since the parameters in a polynomial do not correspond to biologically meaningful attributes and therefore have no underpinning scientific reasoning. This is not to say that another mechanistic model might not describe the functional response with even more accuracy; however it does show the value of having models with a biological basis and provides evidence for their outperforming of phenomenological models.

4.2 The Holling type I response

The discrepancy between the expected and observed numbers of non-filter feeders with a type I functional response could be explained in two ways:

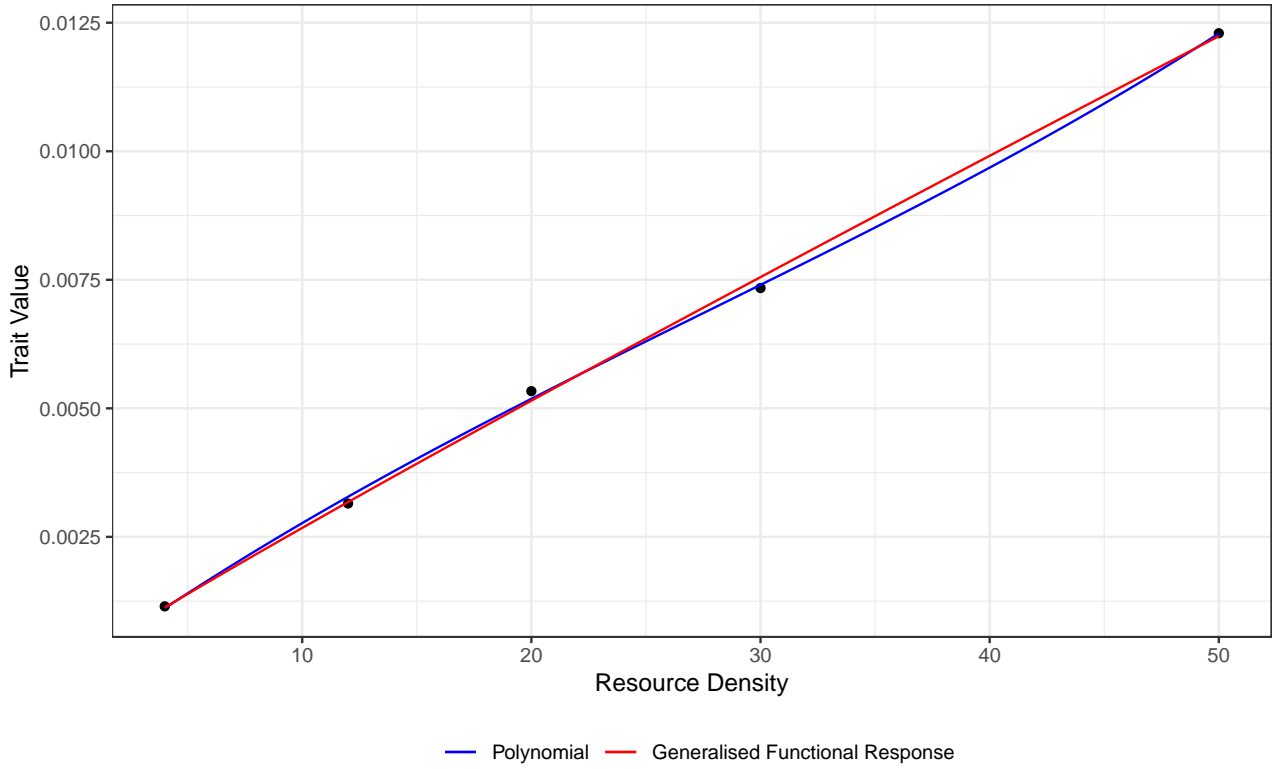

Figure 2: Functional response for a non-filter feeder consumer with Holling I best fit (ID = 39920, $q = -0.055$, $h = 0$)

1) The limiting values of a and h used to subset the Holling type I response from the generalised functional response could have been inadequate, as they were not chosen using a mathematical method. As well as some functional responses being mis-classified as type I, some functional responses that should have been type I may have been missed.

2) Both Holling type II and III functional responses are linear away from the prey density limits. It is possible that not enough data were collected at very low and very high prey densities to display a type II or type III functional response, which is why they have been interpreted as type I.

Several different models have now been produced and further work has been done to refine the Holling models, with modifications to account for both predator and prey size (Aljetlawi, Sparrevik, and Leonardsson 2004), foraging dimensionality (Pawar, Dell, and Savage 2012) and changes over spatial scales (Rincon, Cañas, and Hoy 2017), among others, all of which could impact the results of this study. The work by Seo and DeAngelis in describing the type I response shows a much more complicated dynamical system than formerly hypothesised (Seo and Deangelis 2011), which, if considered in this paper, could have provided evidence for the type I exclusivity to filter feeders. Many different models could further be applied to the empirical dataset to better understand the functional responses of both filter and non-filter feeders.

4.3 The Holling type II and type III responses

Although not an interest of this paper, it is worth noting the high proportion of IDs with a type III response as the best fit, given that type II is considered to be the most common generally (Holling 1959a). This is most likely explained by the strict boundaries imposed between the two types. The fitting and tests done in this paper do not reflect the complexities of the two types or the overlaps that are commonly seen. If the plots of those IDs classed as type III are viewed, it can be seen that many better resemble a type II curve (an example ID is shown in figure 3), suggesting further differentiation is needed than just setting $q \approx 0$. This could be because this work has not taken into account intermediate functional responses, which may better explain much of the dataset than the pure responses (Jeschke, Kopp, and Tollrian 2004).

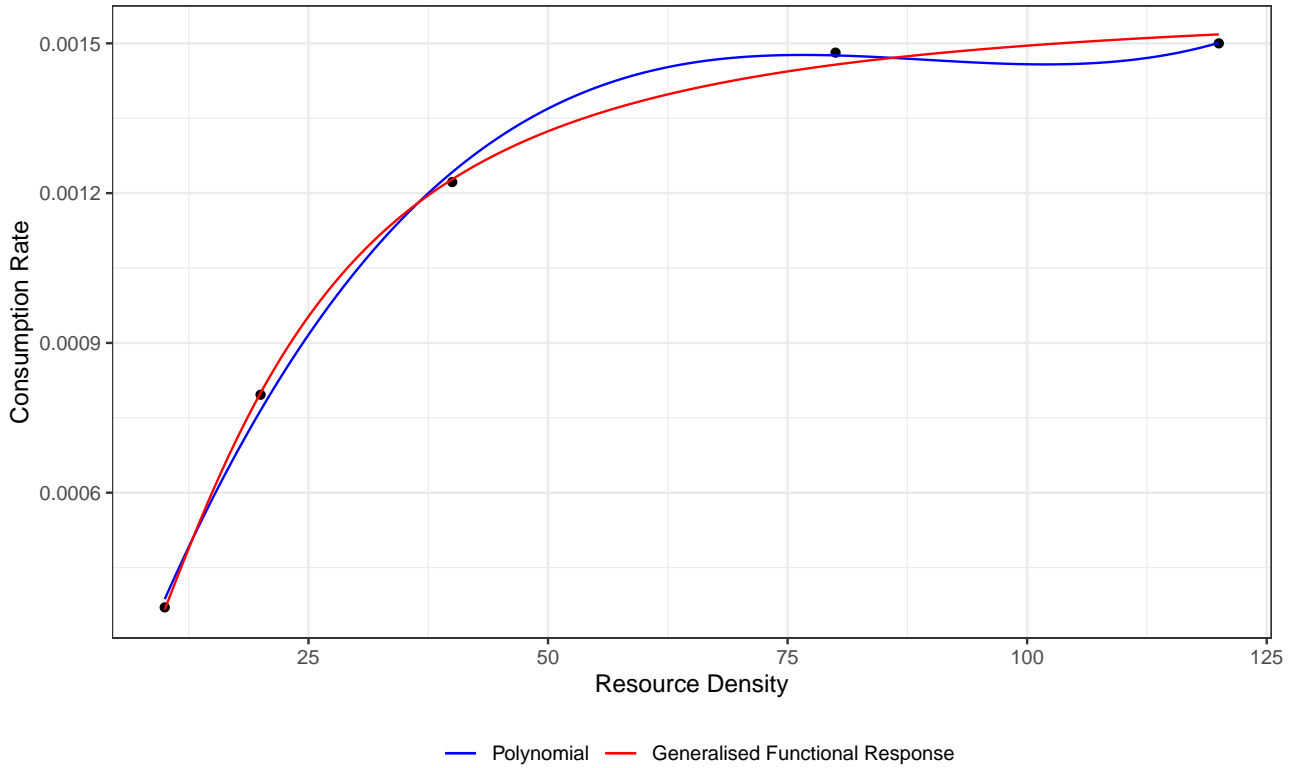

Figure 3: Holling Type II shape for a functional response best fit by a general functional response equation (ID = 39864, $q = 0.764$, $h = 632$)

4.4 Concluding Remarks

In the case of the Holling models and a polynomial, mechanistic models fit significantly better to an empirical dataset than phenomenological models. Although this might not be true for all mechanistic models as it depends on the accuracy of the model in describing nature, this is strong evidence for the superiority of mechanistic models over phenomenological models.

Within the limits of the data provided, a Holling type I response is not exclusive to filter feeders,

203 as has been previously suggested. However this may be due to a number of factors and so further
204 research is required, perhaps using more sophisticated versions of Holling's models, to gain a more
205 accurate picture.
